

# A Sequences Characterization Workflow in a Core Exploration Area, Vaca Muerta System, Neuquén Basin, Argentina

## The Challenge

The Vaca Muerta Formation was deposited in the Neuquén Basin, located in the west-central part of Argentina. It comprises a rock unit with high values of TOC, so it holds great potential as an unconventional shale gas and oil resource play. Together with the Quintuco Formation, it forms a highly geologically complex system, due to its large size and extension.

Like other unconventional resources, the most challenging aspect of developing Vaca Muerta is to optimize the drilling strategy to improve hydrocarbon production, which goes hand in hand with an efficient geological sequence description. Thus, the aim of this study was to characterize the Vaca Muerta system and improve our understanding of the reservoir's characteristics.

## The Solution

Due to the significant scale heterogeneity of the available data in the area of study, it was necessary to adopt a scalable and multi-disciplinary approach, with the goal of integrating sub-millimetric thin sections, seismic data, cores and well logs.

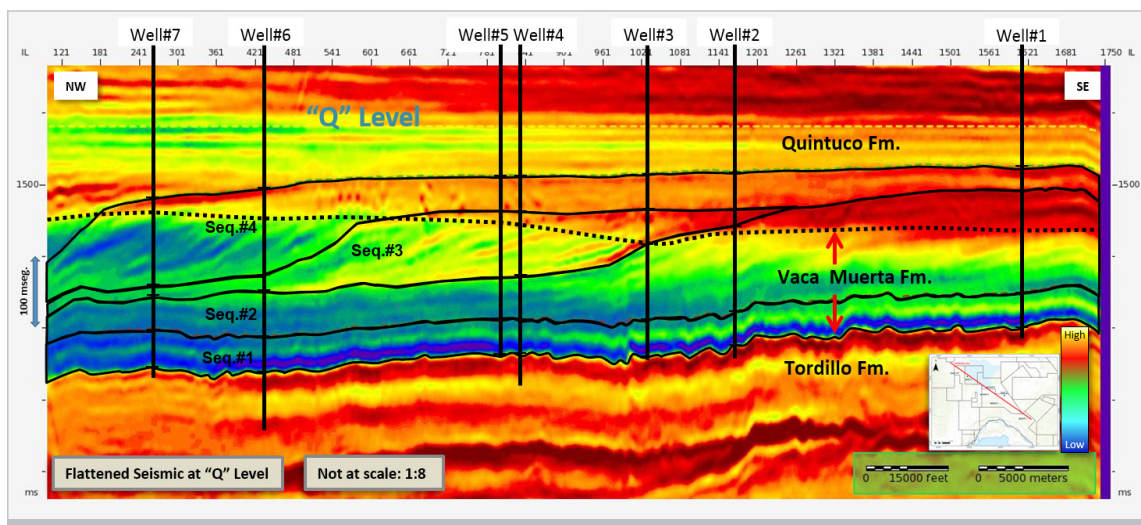

The YPF geoscientists used the Paradigm® SeisEarth® multi-survey, regional-to-prospect interpretation system to perform detailed, multi-scale, structural and stratigraphic interpretation from a very

large dataset. Seismic interpretation was performed on reflection data and reservoir property attributes. It was then correlated with well logs through crossplots, validating the interpretation of well logs with thin sections of core data and cuttings.

All automated and semi-automated processes for interpreting seismic data were easily applied, delivering high quality results within a short period of time.

To reveal the characteristics of the seismic data, the following SeisEarth capabilities were utilized:

- Fast data mining through gathering all data in one dynamic canvas
- A sophisticated 3D environment allowing high-quality display for detailed seismic interpretation
- Interactive work with an unlimited number of attributes; advanced merge options and high-quality rendering through opacity enabled easy adjustment of each attribute
- An advanced interface for high-performance management of routine tasks when working with seismic attributes and seismic interpretation

▲ Acoustic impedance cross section showing sequence distribution in the Vaca Muerta System in the study area. Note the high impedance values towards the top of Sequences #2, #3 and #4 and the low impedance values towards the bottom.

After the Paradigm Seismic Propagator was used to accurately propagate seismic events which correspond to the top of each sequence of interest, a multi-horizon seismic attribute flattening approach allowed the interpreters to perform a more precise investigation into regional geologic sequences and interpret in the flattened space. This stratigraphic interpretation workflow constrained the generation of the final thickness by validating the seismic interpretation.

### The Results

This multi-disciplinary interpretation workflow resulted in the description of four second order sequences in the Vaca Muerta formation; each was described in terms of its own architecture, depositional pattern style, internal litho-stratigraphic configuration and seismic signature.

This result was enabled by simultaneously interpreting different types of seismic attributes using interpretation techniques enabled by the SeisEarth environment. Based on this approach, acoustic impedance was a determining attribute in individualizing the different sequences: Sequence #1 was associated with predominantly low values, while there was a graduation from high

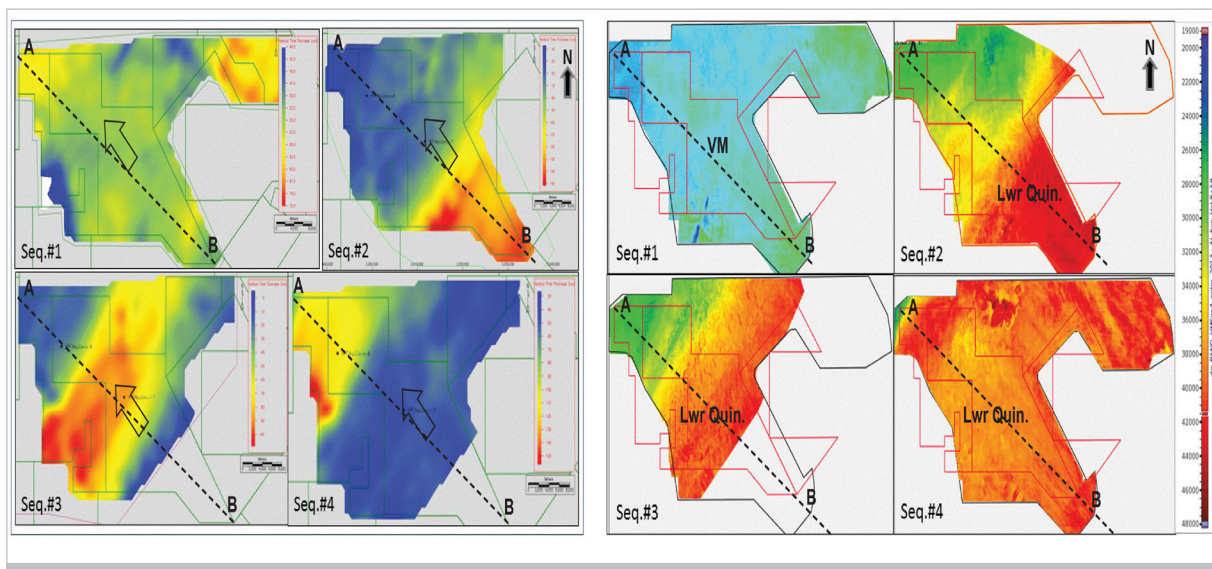

to low in Sequences #2 and #3. Sequence #4 was mainly defined by high values of acoustic impedance.

After defining the stratigraphic sequence correlated with the seismic attributes, it was possible to create a model that matched the geological, well core and production data.

These sequences are now being used by the exploration team to improve the location of future appraisal wells and to prepare development plans. The next step will be to perform correlation of a vertical succession of lithofacies with seismic facies. This will allow the team to define sweet spots in a predictable volumetric distribution, helping them to improve their development strategy.

### The Benefits

This study shed light on the high heterogeneity of the Vaca Muerta Formation, which was previously thought to be simple and homogeneous source rock. This has provided a better understanding of the rock variations, enabling more efficient well stimulations. The visualization and interpretation functionalities in SeisEarth were essential tools for discerning the subtle changes in the rock properties.

*“For over five years, I have used SeisEarth to perform a wide variety of interpretation tasks, including attribute calculation, opacity visualization, multi-3D seismic merge, well path design, flattening, horizon slices, multi-survey visualization, and color palette manipulation. Use of SeisEarth has led to important advances in the exploration of unconventional plays in Argentina.”*

David Guerberoff, YPF Geophysicist
